The following note is useful for this discussion: Note 18.

1. Linear Approximation

A common way to approximate a nonlinear function is to perform linearization near a point. In the case of a one-dimensional function f(x), the linear approximation of f(x) at a point x_* is given by

$$\widehat{f}(x; x_{\star}) = f(x_{\star}) + f'(x_{\star}) \cdot (x - x_{\star}), \tag{1}$$

where $f'(x_*) := \frac{df}{dx}(x_*)$ is the derivative of f(x) at $x = x_*$.

Keep in mind that wherever we see x_{\star} , this denotes a *constant value* or operating point.

We can evaluate the accuracy of our approximation by calculating the approximation error, namely $\left|f(x)-\widehat{f}(x;x_\star)\right|$.

Suppose we have the single-variable function $f(x) = x^3 - 3x^2$. We can plot the function f(x) as follows:

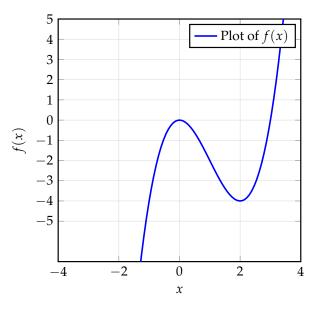

Figure 1: Plot of $f(x) = x^3 - 3x^2$

(a) Write the linear approximation of the function around an arbitrary point x_{\star} . Solution:

$$\widehat{f}(x; x_{\star}) = f(x_{\star}) + f'(x_{\star}) \cdot (x - x_{\star}) \tag{2}$$

$$= f(x_{\star}) + (3x_{\star}^2 - 6x_{\star}) \cdot (x - x_{\star}) \tag{3}$$

(b) Using the expression above, linearize the function around the point $x_* = 1.5$. Draw the linearization into the plot in fig. 1. Then evaluate the accuracy of the linear approximation at x = 1.7 and x = 2.5. Does the difference in accuracy make sense, based on the plot?

Solution:

$$\widehat{f}(x; x_{\star}) = f(1.5) + \left(3 \cdot 1.5^2 - 6 \cdot 1.5\right) \cdot (x - 1.5) \tag{4}$$

$$= -3.375 + (-2.25) \cdot (x - 1.5) \tag{5}$$

The plot is shown below:

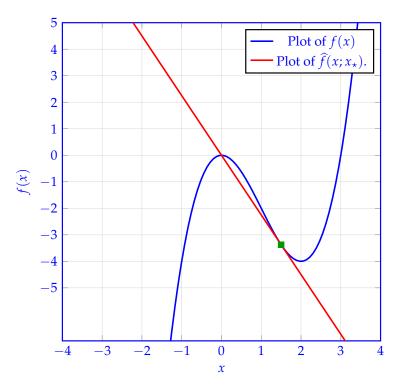

Figure 2: Plot of $\widehat{f}(x; x_{\star})$ and f(x)

To evaluate the accuracy of $\widehat{f}(x; x_{\star})$, we can compute $\left|\widehat{f}(x; x_{\star}) - f(x)\right|$. At x = 1.7:

$$\widehat{f}(1.7; x_{\star}) = -3.375 + (-2.25) \cdot (1.7 - 1.5) \tag{6}$$

$$= -3.375 - 0.45 \tag{7}$$

$$=-3.825$$
 (8)

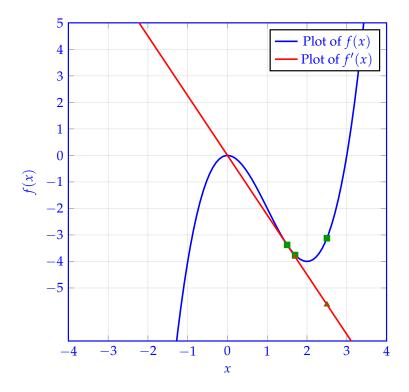

and $f(1.7) = 1.7^3 - 3 \cdot 1.7^2 = -3.757$. Hence, $|\widehat{f}(1.7; x_*) - f(1.7)| = 0.068$. Now, at x = 2.5:

$$\widehat{f}(2.5; x_{\star}) = -3.375 + (-2.25) \cdot (2.5 - 1.5) \tag{9}$$

$$= -3.375 - 2.25 \tag{10}$$

$$=-5.625$$
 (11)

and $f(2.5) = 2.5^3 - 3 \cdot 2.5^2 = -3.125$. Hence, $|\widehat{f}(2.5; x_{\star}) - f(2.5)| = 2.5$. We see that the error at x = 2.5 is about 3 times higher than the error at x = 1.7. We can plot the points x = 1.7 and x = 2.5 on fig. 2 to explicitly see this difference in errors:

Now, we can extend this to higher dimensional functions. In the case of a two-dimensional function f(x,y), the linear approximation of f(x,y) at a point (x_{\star},y_{\star}) is given by

$$\widehat{f}(x,y;x_{\star},y_{\star}) = f(x_{\star},y_{\star}) + \frac{\partial f}{\partial x}(x_{\star},y_{\star}) \cdot (x - x_{\star}) + \frac{\partial f}{\partial y}(x_{\star},y_{\star}) \cdot (y - y_{\star}). \tag{12}$$

where $\frac{\partial f}{\partial x}(x_{\star},y_{\star})$ is the partial derivative of f(x,y) with respect to x at the point (x_{\star},y_{\star}) , and similarly for $\frac{\partial f}{\partial y}(x_{\star}, y_{\star})$

(c) Now, let's see how we can find partial derivatives. When we are given a function f(x,y), we calculate the partial derivative of f with respect to x by fixing y and taking the derivative with respect to x. Given the function $f(x,y) = x^2y$, find the partial derivatives $\frac{\partial f(x,y)}{\partial x}$ and $\frac{\partial f(x,y)}{\partial y}$.

Solution: We have

$$\frac{\partial f(x,y)}{\partial x} = 2xy\tag{13}$$

$$\frac{\partial f(x,y)}{\partial x} = 2xy$$

$$\frac{\partial f(x,y)}{\partial y} = x^2.$$
(13)

(d) Write out the linear approximation of f near (x_*, y_*) .

Solution: Based on the formula in eq. (12), we can write that:

$$\widehat{f}(x, y; x_{\star}, y_{\star}) = f(x_{\star}, y_{\star}) + 2x_{\star}y_{\star} \cdot (x - x_{\star}) + x_{\star}^{2} \cdot (y - y_{\star})$$
(15)

(e) We want to see if the approximation arising from linearization of this function is reasonable for a point close to our point of evaluation. Suppose we want to evaluate the accuracy of our approximation at some point $(x_{\star} + \delta, y_{\star} + \delta)$, where $x_{\star} = 2$ and $y_{\star} = 3$. Find the accuracy of this approximation in terms of δ . What if $\delta = 0.01$?

Solution: The true value of $f(2 + \delta, 3 + \delta)$ is

$$f(2+\delta,3+\delta) = (2+\delta)^2(3+\delta) = (4+4\delta+\delta^2)(3+\delta) = 12+16\delta+7\delta^2+\delta^3$$
 (16)

On the other hand, our approximation is

$$\widehat{f}(2+\delta, 3+\delta; x_{\star}, y_{\star}) = f(2,3) + 2 \cdot 2 \cdot 3 \cdot \delta + 2^{2} \cdot \delta = 12 + 16\delta \tag{17}$$

So the approximation error is

$$\left| f(2+\delta,3+\delta) - \widehat{f}(2+\delta,3+\delta;x_{\star},y_{\star}) \right| = \left| 7\delta^2 + \delta^3 \right| \tag{18}$$

When δ is sufficiently small (i.e. close to 0), the δ^2 and δ^3 terms become very small, and hence our approximation is reasonable. For $\delta=0.01$, the approximation error is $|7\delta^2+\delta^3|=0.000701$.

(f) Suppose we have now a scalar-valued function $f(\vec{x}, \vec{y})$, which takes in vector-valued arguments $\vec{x} \in \mathbb{R}^n$, $\vec{y} \in \mathbb{R}^k$ and outputs a scalar $\in \mathbb{R}$. That is, $f(\vec{x}, \vec{y})$ is $\mathbb{R}^n \times \mathbb{R}^k \to \mathbb{R}$.

One way to linearize the function f is to do it for every single element in $\vec{x} = \begin{bmatrix} x_1 & x_2 & \dots & x_n \end{bmatrix}^\top$ and $\vec{y} = \begin{bmatrix} y_1 & y_2 & \dots & y_k \end{bmatrix}^\top$. Then, when we are looking at x_i or y_j , we fix everything else as constant. This would give us the linear approximation

$$f(\vec{x}, \vec{y}) \approx f(\vec{x}_{\star}, \vec{y}_{\star}) + \sum_{i=1}^{n} \frac{\partial f(\vec{x}, \vec{y})}{\partial x_{i}} \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (x_{i} - x_{i, \star}) + \sum_{i=1}^{k} \frac{\partial f(\vec{x}, \vec{y})}{\partial y_{j}} \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (y_{j} - y_{j, \star}).$$
(19)

In order to simplify this equation, we can define the following two vector quantities:

$$J_{\vec{x}}f = \begin{bmatrix} \frac{\partial f}{\partial x_1} & \cdots & \frac{\partial f}{\partial x_n} \end{bmatrix}$$
 (20)

$$J_{\vec{y}}f = \begin{bmatrix} \frac{\partial f}{\partial y_1} & \cdots & \frac{\partial f}{\partial y_k} \end{bmatrix}$$
 (21)

First, how can we "vectorize" eq. (19) using $J_{\vec{x}}f$ and $J_{\vec{y}}f$? Next, assume that n=k and we define the function $f(\vec{x},\vec{y}) = \vec{x}^{\top}\vec{y} = \sum_{i=1}^{k} x_i y_i$. Find $J_{\vec{x}}f$ and $J_{\vec{y}}f$ for this specific f.

(HINT: For vectorizing, think about replacing the summations as the multiplication of a row and column vector. What would these vectors be?)

Solution: To vectorize eq. (19), we can try to replace the summations with a dot product. That is, if we were to multiply the row vector $\begin{bmatrix} \frac{\partial f}{\partial x_1} \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} & \cdots & \frac{\partial f}{\partial x_n} \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} \end{bmatrix} = J_{\vec{x}} f \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})}$ with the

column vector $\begin{bmatrix} x_1 - x_{1,\star} \\ \vdots \\ x_n - x_{n,\star} \end{bmatrix} = \vec{x} - \vec{x}_{\star}$, then we would get the same summation (and similarly for

 y_i). Writing this more compactly,

$$\widehat{f}(\vec{x}, \vec{y}; \vec{x}_{\star}, \vec{y}_{\star}) = f(\vec{x}_{\star}, \vec{y}_{\star}) + J_{\vec{x}} f \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (\vec{x} - \vec{x}_{\star}) + J_{\vec{y}} f \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (\vec{y} - \vec{y}_{\star})$$
(22)

Now, for the specific $f(\vec{x}, \vec{y})$ in this problem, we apply the definition (and write out the given function explicitly as $x_1y_1 + x_2y_2 + ... + x_ky_k$) to obtain:

$$J_{\vec{x}}f = \begin{bmatrix} y_1 & y_2 & \cdots & y_k \end{bmatrix} = \vec{y}^{\top}$$
 (23)

and

$$J_{\vec{y}}f = \begin{bmatrix} x_1 & x_2 & \cdots & x_k \end{bmatrix} = \vec{x}^{\top}$$
 (24)

(g) Following the above part, find the linear approximation of $f(\vec{x}, \vec{y})$ near $\vec{x}_{\star} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$ and $\vec{y}_{\star} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}$. Recall that $f(\vec{x}, \vec{y}) = \vec{x}^{\top} \vec{y} = \sum_{i=1}^{k} x_i y_i$.

Solution: From the solution in the previous part, we can write

$$\widehat{f}(\vec{x}, \vec{y}; \vec{x}_{\star}, \vec{y}_{\star}) = f(\vec{x}_{\star}, \vec{y}_{\star}) + J_{\vec{x}} f \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (\vec{x} - \vec{x}_{\star}) + J_{\vec{y}} f \Big|_{(\vec{x}_{\star}, \vec{y}_{\star})} (\vec{y} - \vec{y}_{\star})$$
(25)

$$= \vec{x}_{\star}^{\top} \vec{y}_{\star} + \vec{y}_{\star}^{\top} (\vec{x} - \vec{x}_{\star}) + \vec{x}_{\star}^{\top} (\vec{y} - \vec{y}_{\star}) \tag{26}$$

Putting in $\vec{x}_{\star} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$ and $\vec{y}_{\star} = \begin{bmatrix} -1 \\ 2 \end{bmatrix}$,

$$\widehat{f}(\vec{x}, \vec{y}; \vec{x}_{\star}, \vec{y}_{\star}) = 3 + \begin{bmatrix} -1\\2 \end{bmatrix}^{\top} \vec{x} - 3 + \begin{bmatrix} 1\\2 \end{bmatrix}^{\top} \vec{y} - 3$$
(27)

$$= \begin{bmatrix} -1\\2 \end{bmatrix}^{\top} \vec{x} + \begin{bmatrix} 1\\2 \end{bmatrix}^{\top} \vec{y} - 3 \tag{28}$$

These linearizations are important for us because we can do many easy computations using linear functions.
